Pulmonary hypertension was previously considered a rare untreatable condition. The past two decades have seen major changes in our understanding of the spectrum of disease affecting the pulmonary circulation. More than 30 randomised controlled trials (RCTs) of treatments have been performed, and surgery for patients with chronic thromboembolic pulmonary hypertension has been developed. Advances in imaging have enabled more detailed patient assessment, but pulmonary hypertension continues to be a life shortening condition, and there is often a delay of around two years from onset of symptoms to diagnosis.[1] This article focuses on adult pulmonary hypertension in primary and secondary care, its diagnosis, and management.

What is pulmonary hypertension and how common is it?

Pulmonary hypertension is defined at cardiac catheterisation as a mean pulmonary artery pressure of 25 mm Hg or more. The initial clinical classification in 1973 arose from a World Health Organization sponsored international meeting after an epidemic related to use of the appetite suppressant, aminorex fumarate.[2] It defined primary pulmonary hypertension (now termed idiopathic pulmonary arterial hypertension) as being characterised by vasculopathy of the pulmonary arteries. Better understanding of disease mechanisms led to subsequent classification of conditions with shared clinical and pathophysiological characteristics:

Group 1: Pulmonary arterial hypertension (PAH), which can be idiopathic (IPAH) or associated with other conditions, notably systemic sclerosis and congenital heart disease

Group 2: Pulmonary hypertension owing to left heart disease (PH-LHD)

Group 3: Pulmonary hypertension owing to lung disease or hypoxia (PH-Lung), or both

Group 4: Chronic thromboembolic pulmonary hypertension (CTEPH)

Group 5: Unclear or multifactorial mechanisms (fig 1⇓).[3]

Many mechanisms can lead to elevation of pulmonary pressures. In PAH, progressive narrowing of the pulmonary arterial bed results from an imbalance of vasoactive mediators, including prostacyclin, nitric oxide, and endothelin-1. This leads to an increased right ventricular afterload, right heart failure, and premature death. Between 11% and 40% of patients with IPAH and 70% of patients with a family history of PAH carry a mutation in the gene encoding bone morphogenetic receptor-2 (*BMPR2*); however, penetrance is low—carriers have a 20% lifetime risk of developing pulmonary hypertension.[4 5] Therefore, "multiple hits" are probably needed for the development of PAH. In PH-LHD, raised left atrial pressures result in secondary elevation of pulmonary pressure. In PH-Lung, raised pulmonary arterial pressures result from mechanisms such as vascular destruction and hypoxic vasoconstriction. In CTEPH, mechanical obstruction of the pulmonary vascular bed is the primary process.

Incidences are estimated to be 1-3.3 per million per year for IPAH and 1.75-3.7 per million per year for CTEPH; the prevalence of PAH is estimated at 15-52 per million.[6-10] Pulmonary hypertension is more common in severe respiratory and cardiac disease, occurring in 18-50% of patients assessed for transplantation or lung volume reduction surgery, and in 7-83% of those with diastolic heart failure.[11-14]

Who gets pulmonary hypertension and why is classification important?

IPAH is rare and primary care doctors may never encounter a case. By contrast, the prevalence of PAH is high in certain patient groups, such as those with systemic sclerosis (9%), portal hypertension (2-6%), congenital heart disease (5-10%), and HIV (0.5%).[15-20] Between 0.5% and 4% of patients develop CTEPH after acute pulmonary embolism; patients at increased risk include those presenting with large, recurrent, or unprovoked clots.[21 22] Classification is crucial in determining treatment and prognosis.[9] Specific treatments exist for PAH and CTEPH. By contrast, in PH-LHD and PH-Lung, treatment is best directed at the underlying condition, and currently PAH

Summary points

Pulmonary hypertension has many causes so prognoses and treatments vary

The condition is diagnosed by systematically evaluating the breathless patient and screening patients at high risk

Patients at high risk of severe and treatable pulmonary hypertension include those with systemic sclerosis, portal hypertension, congenital heart disease, and previous pulmonary embolism

Specialist centres provide access to tailored investigative and treatment pathways and support networks for patients

Patients with severe pulmonary hypertension can deteriorate rapidly—do not delay referral to perform specialist investigations

Only selected patients with pulmonary arterial hypertension and chronic thromboembolic pulmonary hypertension benefit from interventions directed at pulmonary vasculature; for most patients treatment is aimed at the underlying condition

Sources and selection criteria

This review is based on our personal experience, personal archives of references, and a PubMed search using terms including pulmonary hypertension, chronic thromboembolic disease, and prognosis. We consulted international guidelines from the European Society of Cardiology, European Respiratory Society, and American College of Chest Physicians.

specific treatments are not recommended. Distinguishing between IPAH and PH-LHD due to diastolic dysfunction in the setting of normal left ventricular systolic function may be challenging (table 1⇓).

Median survival in untreated IPAH is 2.8 years, but more recent registries have observed overall median survival of at least five years.[9] [23] In the past, the mean age at diagnosis in IPAH was 35 years; current five year survival in this younger age group is now about 75%.[10] PAH associated with systemic sclerosis carries a worse prognosis than IPAH, whereas the opposite is true for congenital heart disease.[9] The development of pulmonary hypertension in cardiac and respiratory disease has a negative impact on prognosis, which depends on the underlying cause and severity of pulmonary hypertension.

What are the symptoms and signs of pulmonary hypertension?

PAH most commonly presents with progressive breathlessness.[24] As right ventricular dysfunction develops patients can experience exertional dizziness and syncope. Oedema and ascites occur late in the disease. Anginal chest pain may occur due to exertional myocardial hypoperfusion in the setting of right ventricular hypertrophy, left main coronary artery compression by the pulmonary artery, or ischaemic heart disease.[25] Patients are prone to tachyarrhythmias, most commonly atrial flutter, which can cause sudden decompensation.[26] Haemoptysis, although uncommon, can occur in Eisenmenger's syndrome and CTEPH, where bronchial arteries may be enlarged. Signs suggestive of pulmonary hypertension include a loud pulmonary second heart sound, systolic murmur of tricuspid regurgitation, raised jugular venous pressure, peripheral oedema and ascites, but these signs may be subtle or absent in early disease. Look for signs of associated conditions (such as connective tissue disease or liver disease).

When should I suspect pulmonary hypertension?

Pulmonary hypertension is diagnosed by systematically evaluating the breathless patient and screening high risk groups. Unexplained progressive exertional breathlessness in the absence of symptoms or signs of respiratory or left heart disease is suggestive. Screening protocols exist for high risk groups. Rheumatology centres screen patients with systemic sclerosis annually, and potential liver transplant recipients are routinely investigated for portopulmonary hypertension. Persistent breathlessness after pulmonary embolism should alert the doctor to the possibility of CTEPH.

What investigations should I perform if pulmonary hypertension is suspected?

Electrocardiography, chest radiography, and pulmonary function tests may identify an alternative cause of breathlessness (fig 2⇓). Evidence of right heart strain on electrocardiography and prominent pulmonary arteries or cardiomegaly on chest radiography were seen in 80-90% of cases in a large IPAH registry.[24] In clinical practice, however, a normal electrocardiograph and chest radiograph cannot exclude the diagnosis. A reduction in gas transfer (lung capacity to "transfer" an inhaled gas into the blood) and mildly deranged spirometry both occur in IPAH.[27] If pulmonary hypertension is still suspected, echocardiography should be performed.[28] Figure 3⇓ describes the estimation and interpretation of systolic pulmonary artery pressure, together with other echocardiographic features suggesting the presence of pulmonary hypertension. Importantly, pulmonary hypertension is defined by mean pulmonary artery pressure (measured at right heart catheterisation) not systolic pulmonary artery pressure (estimated by echocardiography). In addition, systolic estimates are less accurate in respiratory disease and during intercurrent illness.[14]

How is pulmonary hypertension assessed in a specialist unit?

If initial investigations suggest that pulmonary hypertension is possible, further tests are needed to confirm the diagnosis and to establish cause and severity. In the United Kingdom, a network of specialist centres was commissioned in 2001 to standardise and improve care (box 1). If severe disease is suspected, do not delay referral to a specialist centre, although imaging to exclude thromboembolic disease may be considered. If the degree of pulmonary hypertension seems to be disproportionate to the underlying cardiorespiratory disease, or if diagnostic doubt exists, discussion with a specialist centre is recommended. In these groups it is also important to exclude coexisting thromboembolic disease as a cause of pulmonary hypertension. Accurate classification and assessment of disease severity (fig 2) requires integration of clinical, physiological, and radiological data. This is central to further management (fig 4⇓).

Blood, exercise testing, and overnight oximetry

Immunological and HIV testing may identify a cause of pulmonary hypertension. Brain natriuretic peptide (BNP) and N-terminal-pro-BNP have prognostic importance. Lower levels at baseline and improvement during follow-up are associated with better outcomes.[29][30] The six minute walk test has been extensively evaluated. It provides functional and prognostic information and can be used to monitor treatment response.[31][32] Cardiopulmonary exercise testing in selected patients gives more detailed physiological and prognostic information.[33] Overnight oximetry is performed if sleep disordered breathing is a suspected cause.

Imaging

Isotope perfusion lung scanning has high sensitivity for CTEPH and a normal scan excludes the diagnosis, whereas increased renal isotope uptake may identify right to left shunts and explain hypoxaemia.[34][35] High resolution computed tomography and computed tomography pulmonary angiography visualise the pulmonary arterial tree and provide a wealth of additional diagnostic information (fig 5⇓). Direct features of chronic thromboembolic disease include occlusions, stenoses, and intraluminal webs (fig 1), whereas indirect signs include a mosaic perfusion pattern. These signs can be subtle and may be missed by a non-specialist radiologist. Magnetic resonance imaging provides a radiation-free method of quantitatively assessing cardiac structure and function, prognosis, and response to treatment.[36][37] Magnetic resonance pulmonary angiography can supplement computed tomography pulmonary angiography in the assessment of CTEPH operability, and magnetic resonance perfusion imaging is as sensitive as isotope perfusion lung scanning.[38][39] Pulmonary angiography is not commonly used in the UK to select CTEPH patients for pulmonary endarterectomy, but is used widely in other centres throughout the world to assess for surgical accessibility.

Right heart catheterisation

If non-invasive investigations support a diagnosis of pulmonary hypertension, right heart catheterisation is needed to confirm the diagnosis by directly measuring pulmonary pressure. It also allows measurement of cardiac output and estimation of left atrial pressure using pulmonary arterial wedge pressure.

Haemodynamic parameters (such as right atrial pressure, cardiac index, and pulmonary vascular resistance) and pulmonary artery saturations have important prognostic value. Raised pulmonary arterial wedge pressure is suggestive of PH-LHD. Changes in oxygen saturations between right sided cardiac chambers may suggest an intracardiac shunt. Vasoreactivity testing, usually using inhaled nitric oxide, can identify patients with IPAH who may respond to long term high dose calcium channel blockers. A positive response is defined as a reduction in mean pulmonary artery pressure of at least 10 mm Hg, to less than 40 mm Hg, without a fall in cardiac output.[40]

What treatments are available for pulmonary hypertension?

Supportive treatment

Patients with CTEPH require anticoagulants because of the central role of thromboembolic disease. Although anticoagulation is recommended in IPAH, its role in PAH associated with other conditions is less clear.[41][42] Diuretics are often needed to treat heart failure. Digoxin and long term oxygen therapy may be considered, but there is no evidence from RCTs on their use. Annual flu vaccination is recommended.[43] Pregnancy is poorly tolerated despite changing practices,[44] and a recent systematic review found that maternal mortality remains high (17-33%).[45] Women are counselled about the high risks and are offered effective contraception; termination is recommended if pregnancy occurs.[43] Progesterone-only contraceptives—oral desogestrel, intramuscular medroxyprogesterone, and etonogestrel implants—avoid the prothrombotic effects of combined oral contraceptives. The levonorgestrel releasing coil is effective, but poor tolerance of potential vasovagal episodes mandates insertion in hospital. Emergency hormonal contraception is safe after unprotected intercourse. Non-obstetric surgical intervention also poses risks and its indication requires careful evaluation.

Specific medical treatment (table 2⇓)

High dose calcium channel blockade

About 10% of patients with IPAH have a positive response to vasoreactivity testing at right heart catheterisation. Observational studies suggest that half of these patients exhibit long term clinical responses to high dose calcium channel blockade (such

as diltiazem titrated to 480-720 mg/day or nifedipine titrated to 60-120 mg/day), with near normalisation of prognosis.[46][47] No evidence exists for this treatment in other forms of PAH, and because of the potential negative inotropic effect, treatment should not be started without a positive acute vasoreactive test.

Prostanoids

Prostacyclin is a vasodilator with antiproliferative effects. Infused continuously through an indwelling central line, it was the first PAH specific drug shown to be efficacious in a small RCT, demonstrating improvements in exercise capacity, haemodynamics, and, uniquely, survival.[48] It has a half life of about six minutes, is unstable at room temperature, and intravenous administration has an associated risk of line infection. Alternative routes of administration were therefore developed. A larger RCT found that nebulised iloprost (half life about 30 minutes) improved exercise capacity and haemodynamics when given seven times a day.[49] Because of its superior stability, iloprost is also given intravenously in some centres. Treprostinil (half life about four hours) was shown, in a very large RCT, to significantly improve exercise capacity when given by continuous subcutaneous infusion.[50] Further RCTs also showed significant improvements in exercise capacity when it was given by nebulised and intravenous routes.[51][52] Oral prostanoids have also been assessed with large RCTs, but results have generally been disappointing, and studies are ongoing.[53-56]

Endothelin receptor antagonists

Endothelin is a potent vasoconstrictor of vascular smooth muscle. Two oral endothelin receptor antagonists are currently licensed, bosentan and ambrisentan, on the basis of well conducted RCTs showing improved exercise capacity and time to clinical worsening.[57][58] Bosentan causes reversible abnormalities in liver function tests in 5-10% of patients, so monthly monitoring is needed.[59]

Phophodiesterase-5 inhibitors

Nitric oxide acts via cyclic GMP to increase pulmonary vascular relaxation and reduce cellular proliferation and is degraded by phophodiesterase-5. Two oral phophodiesterase-5 inhibitors (sildenafil and tadalafil) improved exercise and functional capacity in large well conducted RCTs.[60][61] These drugs have important interactions with nitrates, so concomitant use is contraindicated.

Treatment approach

Guidelines suggest starting oral treatment for patients with PAH in WHO functional classes II and III, and considering parenteral prostanoids in suitable patients in class IV or those with poor prognostic markers in class III (box 2).[43] If response to treatment is suboptimal, switching or adding further drugs is suggested.[43] Sequential addition of drugs to achieve predefined treatment goals in six minute walk distance, maximal oxygen capacity, and peak systolic blood pressure was associated with improved outcome compared with patients whose treatment had been escalated in a non-standardised manner.[62] Several RCTs of combination therapy are ongoing. Assessment of the patient's ability to use complex prostanoid therapy and adherence to treatment require the support of experienced healthcare professionals.

Chronic thromboembolic pulmonary hypertension

About two thirds of patients with CTEPH are candidates for pulmonary endarterectomy. This operation offers the best prospect of substantial improvement in symptoms, haemodynamics, and long term survival, as shown by a recent UK observational study.[8] Surgical eligibility criteria are not clearly established, and suitable candidates are identified after assessment at specialist surgical centres (Papworth Hospital in the UK). Perioperative mortality in large volume centres is now less than 5%. In inoperable cases PAH specific drugs are often used, although evidence is suboptimal. Do not delay referral for surgery for trials of medical therapy, although such treatment can be used to support patients with severe CTEPH as a "bridge" to surgery.

Other non-medical treatments

Lung transplantation (usually double lung), which has overall five year survival of around 50%, is indicated in severe PAH or inoperable CTEPH if medical management fails.[63] Atrial septostomy decompresses the pressure loaded heart and may be useful in patients with severe PAH who have intractable syncope but not severe hypoxaemia, or as a bridge to transplantation.[64] Supervised exercise training improves exercise capacity, but effects on haemodynamics and prognosis are unclear.[65]

What challenges are on the horizon?

Despite progress in the management of PAH, it remains a life shortening condition. Understanding disease mechanisms and developing new treatments is a focus of international collaboration. Recent data have shown efficacy for drugs targeting existing pathways, such as macitentan (endothelin receptor antagonist)[66] and riociguat (nitric oxide pathway via soluble guanylate cyclase stimulation).[67][68] Selexipag,[69] a prostacyclin receptor agonist, is also under investigation. Despite promising effects on pulmonary haemodynamics the tyrosine kinase inhibitor, imatinib, has recently been withdrawn from licensing application, partly because of safety concerns.[70] Studies with stem cell therapy are ongoing.[71] The role of mechanical treatments, such as cardiac resynchronisation and right ventricular assist devices, in PAH are of interest.[72][73] The optimal treatment of PH-LHD and PH-Lung is unclear and drugs are being studied in phase III trials. Pulmonary artery balloon angioplasty is being investigated in patients with CTEPH who are not amenable to pulmonary endarterectomy.[74] Future availability of generic oral drugs for pulmonary hypertension may lead to inappropriate prescribing in PH-LHD and PH-Lung. It may also increase late referral to specialist centres and delays in escalation of treatment.

Improved diagnostics and treatments provide increasingly complex choices for patients and healthcare professionals in this rare illness. The delivery of care through specialist centres is increasingly advocated worldwide as a cost effective way to deliver high quality care.[43] Education on disease trajectory, provision of psychological support, and access to social and end of life care are championed by patients and their representative organisations, and they are key to improving the quality of life for patients with pulmonary hypertension.[75]

Box 2 WHO functional classes

Class I: Patients with pulmonary hypertension but in whom ordinary physical activity does not cause undue symptoms

Class II: Patients with pulmonary hypertension resulting in slight limitation of physical activity. They are comfortable at rest but ordinary physical activity causes undue dyspnoea or fatigue, chest pain, or near syncope

Class III: Patients with pulmonary hypertension resulting in marked limitation of physical activity. They are comfortable at rest but less than ordinary activity causes undue dyspnoea or fatigue, chest pain, or near syncope

Class IV: Patients with pulmonary hypertension who cannot carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnoea or fatigue may be present at rest. Discomfort is increased by any physical activity

---

Tips for non-specialists

Consider pulmonary hypertension as a cause of progressive unexplained breathlessness

Echocardiography is the most useful non-invasive test for investigating pulmonary hypertension but estimates systolic, not mean, pulmonary artery pressure

Computed tomography pulmonary angiography is useful for assessing suspected pulmonary hypertension and also allows estimation of cardiac chamber size

A large left atrium suggests that pulmonary hypertension is more likely to be caused by left heart disease

Pulmonary hypertension should not be empirically treated until a clear diagnosis is established

If a patient has suspected severe pulmonary hypertension remember that the differential diagnosis is wide and outlook has improved considerably over the past 10 years

Tables

Table 1| **Pulmonary hypertension in patients with normal left ventricular systolic function: features useful in discriminating between idiopathic pulmonary arterial hypertension and pulmonary hypertension caused by left ventricular diastolic dysfunction**

Factor	Idiopathic pulmonary arterial hypertension	Diastolic dysfunction
Age	Younger	Older[9]
Comorbidities	None	Essential hypertension, atrial fibrillation, diabetes[76]
Electrocardiography	Right axis deviation, right ventricular hypertrophy, ST depression inferiorly and anteriorly	Left axis deviation, left ventricular hypertrophy, ST depression laterally
Echocardiography		
Left atrial size	Normal	Large[76]
Mitral flow and tissue Doppler	Normal	E/E′ >15*[77]
Cardiac magnetic resonance imaging		
Morphology	Ventricular mass index† often raised	Ventricular mass index† often normal[37]
Septal position	Systolic eccentricity index‡ often raised	Systolic eccentricity index‡ often normal[37]
Function	Right ventricular function often moderately or severely impaired	Right ventricular function often normal or mildly impaired[37]
Right heart catheter:	Pulmonary arterial wedge pressure normal	Pulmonary arterial wedge pressure raised[43]

*Ratio of mitral peak velocity of early filling (E) to early diastolic mitral annular velocity (E′); †Ratio of right ventricular mass to left ventricular mass; ‡Ratio of maximal short axis left ventricular diameters parallel and perpendicular to interventricular septum.

Table 2| Licensed drugs for treating pulmonary hypertension

| Drug	Randomised controlled trial	Administration	Important or common side effects	Important complications
Prostanoid				
Epoprostenol	Barst and colleagues[48]	Intravenous	Nausea, headache, leg pain, jaw pain, flushing, diarrhoea	Line infection
Iloprost	AIR[49]	Nebuliser; intravenous	As for eposprostenol but less severe when nebulised	Line infection with intravenous administration
Treprostinil	Simonneau and colleagues[50]	Subcutaneous	As for eposprostenol; infusion site pain for subcutaneous administration	
	TRIUMPH[51]	Nebuliser; intravenous		
	TRUST[52]			
Endothelin receptor antagonists				
Bosentan	BREATHE-1[57]	Oral		Abnormal liver function tests in 10% of patients; teratogenecity
Ambrisentan	ARIES-1 and 2[58]	Oral	Peripheral oedema	
Phosphodiesterase-5 inhibitors				
Sildenafil	SUPER-1[60]	Oral	Headache, indigestion, nasal stuffiness, blurred vision, visual colour change	Non-arteritic ischaemic optic neuropathy
Tadalafil	PHIRST[61]			

Figures
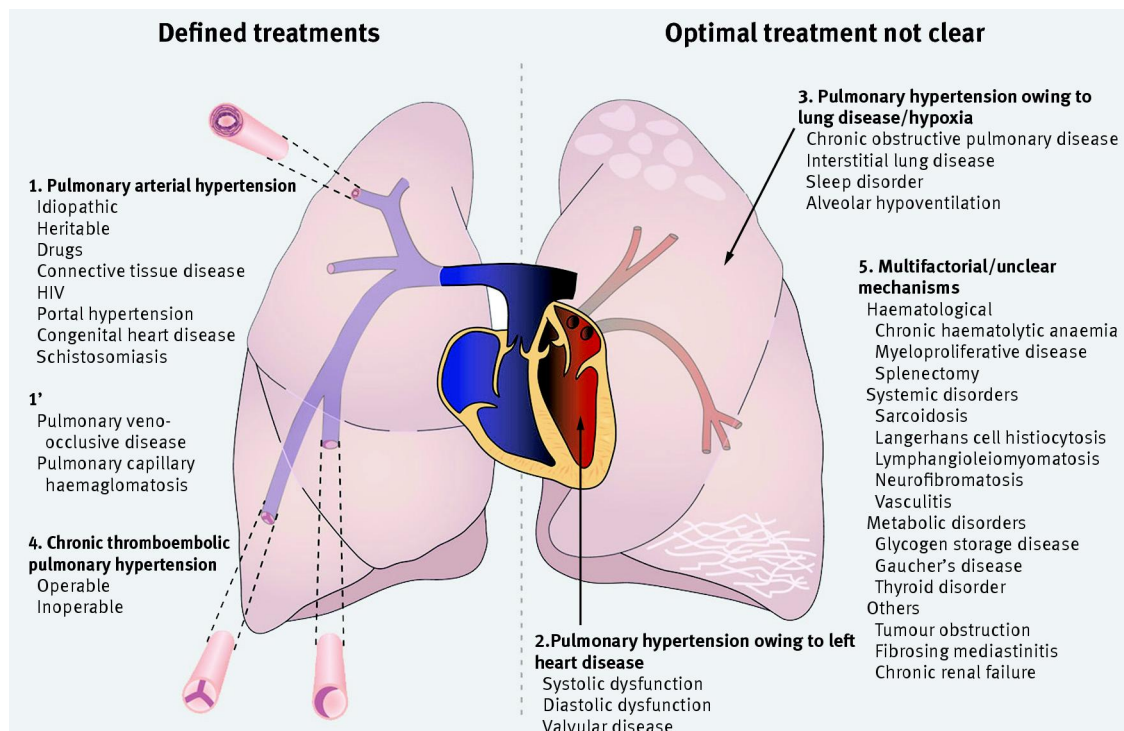

Fig 1 Classification of adult pulmonary hypertension. The condition can be caused by narrowing of the pulmonary arterial tree as a result of vasculopathy (group 1) or webs and stenoses of chronic thromboembolic disease (group 4). Optimal treatments are generally defined for groups 1 and 4. More commonly, it is associated with left heart disease (group 2) or lung disease (group 3), and optimal treatments are unclear. Several conditions associated with pulmonary hypertension have multifactorial or unclear mechanisms (group 5). *Chronic haemolytic anaemia will probably be in group 5 in next classification update

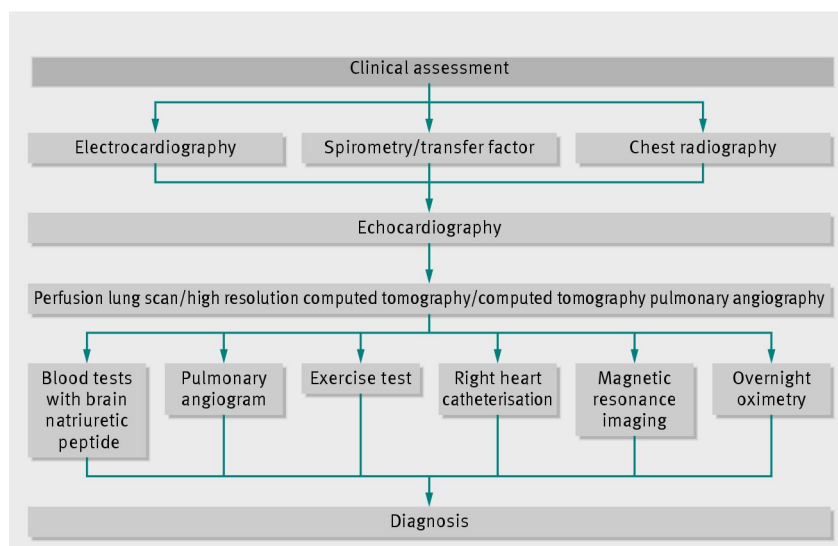

Fig 2 Diagnostic pathway for patients with suspected pulmonary hypertension

Estimation of systolic pulmonary arterial pressure (sPAP)
 Maximal tricuspid regurgitant jet velocity (V) measured using
  continuous wave Doppler
 RV systolic pressure (RVSP) calculated using equation:
  $RVSP = 4V^2$
 sPAP = RVSP + right atrial pressure (RAP)
 RAP estimated at 5 mm Hg unless size of interventricular
  septum suggests higher
 In this example $sPAP = 4 \times (4.8)^2 + RAP = 92$ mm Hg + RAP

Other features suggestive of pulmonary hypertension
 Dilated right sided chambers
 Reduced RV function
 RV hypertrophy
 Enlarged pulmonary artery
 Abnormal interventricular septal motion

Likelihood of pulmonary hypertension
 Pulmonary hypertension unlikely
  sPAP ≤36 mm Hg* with no other features of pulmonary
  hypertension
 Pulmonary hypertension possible
  sPAP ≤36 mm Hg* + other features of pulmonary hypertension
  sPAP 37-50 mm Hg*
 Pulmonary hypertension likely
  sPAP >50 mm Hg*

 *including 5 mm Hg RAP

Fig 3 Echocardiographic assessment of pulmonary hypertension. RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle
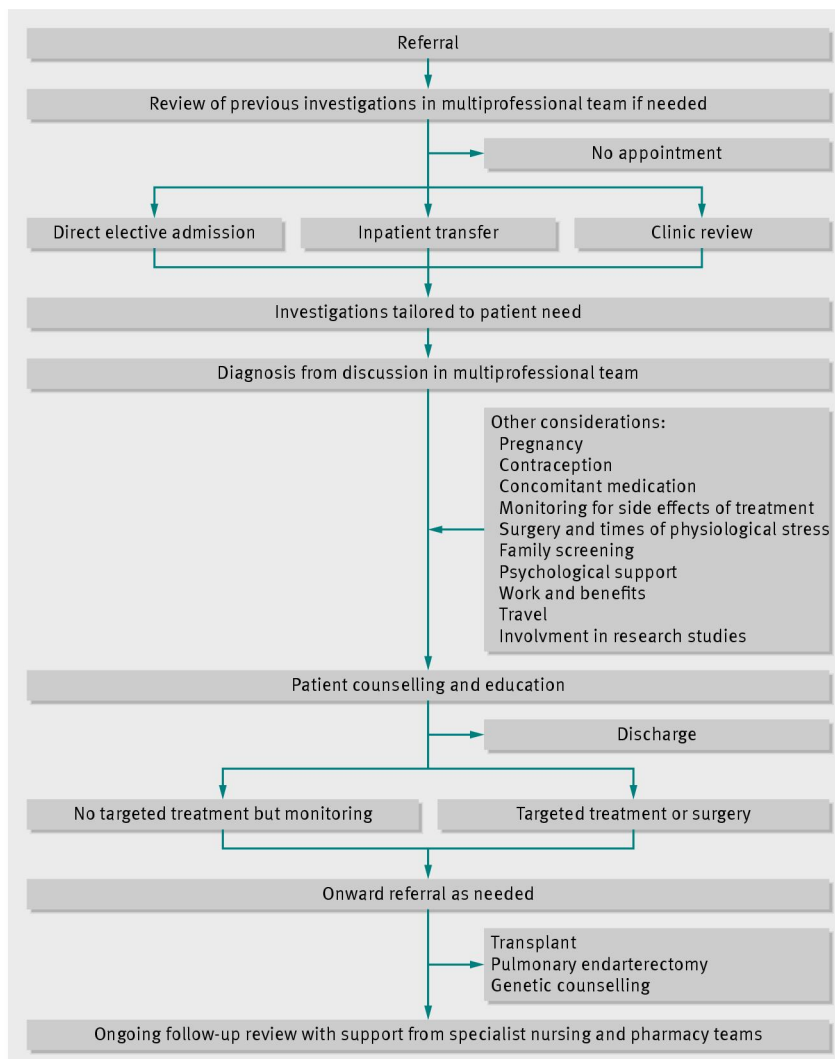

Fig 4 Overview of patient pathway at a specialist centre

Features on this image
Dilation of right sided chambers
Flattening/posterior bowing of interventricular septum
Presence of chronic thromboembolic disease in both lower
  lobe pulmonary arteries
Normal sized left atrium

**Other features that may be demonstrated using computed
tomography pulmonary angiography**
Pulmonary artery: ascending aorta >1 suggestive of pulmonary
  hypertension
Right ventricular hypertrophy
Underlying lung disease
Dilated left atrium and normal right ventricle in pulmonary
  hypertension of the left heart
Mosaic parenchymal perfusion in CTEPH
Congenital heart disease
  Anomalous pulmonary venous drainage
  Patent ductus arteriosus
Bronchial artery hypertrophy in Eisenmenger's syndrome and
  CTEPH
Dilated oesophagus in systemic sclerosis
Splenomegaly in porto-pulmonary hypertension

Fig 5 Computed tomography assessment of pulmonary hypertension. RA=right atrium; RV=right ventricle, LA=left atrium; LV=left ventricle; IVS, interventricular septum; PA, pulmonary artery; Ao, aorta; CTEPH=chronic thromboembolic pulmonary hypertension
